The interplay of structure, magnetism and superconductivity has been a recurrent theme in the study of iron-based superconductors[1]. Among these systems, PbO-type β-FeSe has the simplest crystallographic structure and a rich phase diagram[1]. It undergoes a structural phase transition, similar to that of many parent compounds of the 1111 and 122 iron-based systems, at \( \sim 90 \) K. In these later materials, structural and magnetic order track each other closely, which has led to the suggestion of a magnetic (spin-nematic) origin of the structural distortion[2]. In FeSe, however, no static magnetism is found at ambient pressure[3, 4] and spin-fluctuations are found to be enhanced only at low temperatures[5], which raises the question of the origin of the structural transition. FeSe becomes superconducting at a modest \( T_c = 8 \) K[6], yet the onset of superconductivity rises dramatically to \( \sim 37 \) K under hydrostatic pressure[7, 8], which also induces static magnetic order[9]. Recently, superconductivity even up to over 50 K was demonstrated in strained epitaxial thin films[10]. With its huge sensitivity to external pressure and the large separation in the tetragonal state and do not undergo structural transformations or decomposition reactions. Wave-length dispersive x-ray spectroscopy reveals an impurity level below 500 ppm, in particular there is no evidence for Cl, Si, K or Al impurities.

Fe and Se powders were mixed in an atomic ratio 1:1 and sealed in an evacuated SiO\(_2\) ampoule together with a eutectic mixture of KCl and AlCl\(_3\). The ampoule was heated to 390°C on one end while the other end was kept at 240°C. After 28.5 days isometric FeSe crystals with tetragonal morphology were extracted at the colder end (Fig. 1 (a,b)). At such low temperatures, samples form directly in the tetragonal state and do not undergo structural transformations or decomposition reactions. Wave-length dispersive x-ray spectroscopy reveals an impurity level below 500 ppm, in particular there is no evidence for Cl, Si, K or Al impurities.

x-ray powder diffraction confirms the tetragonal structure with lattice constants \( a = 3.7707(12) \) Å and \( c = 5.521(3) \) Å. Structural refinement with a 4-circle diffractometer using Mo-radiation yields a composition of Fe:Se=0.995(4):1 (i. e. stoichiometric within the error

The initial Se content is low enough, can tetragonal β-FeSe be obtained, however, only in the form of a platelet of hexagonal morphology which contains both, tetragonal β-FeSe and magnetic Fe\(_7\)Se\(_8\)[15].

In this Letter, we report on high-resolution thermal-expansion of vapor-grown single-crystalline β-FeSe. Growth directly in the tetragonal structure results in high quality single-crystals, which are well suited to study the anisotropy of pressure effects; a necessary complement to hydrostatic-pressure studies in any non-cubic material. We show that the dramatic increase of \( T_c \) under hydrostatic pressure arises from a reduction of the in-plane area, while \( T_c \) is five times less sensitive to the \( c\)-axis length. Further, we demonstrate non-Fermi-liquid behavior in the low-temperature in-plane thermal-expansion coefficients, which slightly reduces the orthorhombic distortion and presumably arises from low-temperature spin-fluctuations. Surprisingly, orthorhombic distortion and superconductivity do not compete in FeSe, in contrast to underdoped 122 pnictides, which suggests that the structural transition may not be of magnetic origin.

The interplay of structure, magnetism and superconductivity has been a recurrent theme in the study of iron-based superconductors[1]. Among these systems, PbO-type β-FeSe has the simplest crystallographic structure and a rich phase diagram[1]. It undergoes a structural phase transition, similar to that of many parent compounds of the 1111 and 122 iron-based systems, at \( \sim 90 \) K. x-ray powder diffraction confirms the tetragonal structure with lattice constants \( a = 3.7707(12) \) Å and \( c = 5.521(3) \) Å. Structural refinement with a 4-circle diffractometer using Mo-radiation yields a composition of Fe:Se=0.995(4):1 (i. e. stoichiometric within the error
the volume average of the thermal expansion indicates $\Delta a^c_{[100]}$ the tetragonal axis is measured\cite{17}. Measuring thermal expansion along the applied force and the (shorter) orthorhombic $b$ axis (inferred) does not couple strongly to hydrostatic pressure.

No distinct second, potentially magnetic, phase transition is observed below $T_s$. At $T_s = 7.75$ K, the discontinuity in the in-plane thermal-expansion coefficients $\Delta \alpha_i$ (kink in $\Delta L_i(T)$) clearly confirms a sharp, bulk superconducting transition. $\Delta \alpha_i$ is related to the uniaxial pressure derivative of $T_c$ via the Ehrenfest relationship

$$\frac{dT_c}{dp_i} = \frac{V_m}{C_p/T_c} \Delta \alpha_i$$

$V_m = 23.34$ cm$^3$/mol is the molar volume and $\Delta C_p/T_c = 9.45(30)$ mJ mol$^{-1}$K$^{-2}$ is the specific heat jump, which we take from Reference\cite{19} We thus obtain $\frac{dT_c}{dp_{ab}} = 2.6(3)$K/GPa for the in-plane average, $\frac{dT_c}{dp_{c}} = 2.2(5)$ bar) and a structural $z$ parameter of $z = 0.26668(9)$. No indications for interstitial atoms were found. Fig. 1 (c) shows the temperature dependence of the magnetic susceptibility with field applied parallel to the $ab$ plane. The inset shows the low-temperature data in a field of 20 mT. The screening is larger than $-1$ because of the demagnetizing effect.

Fig. 2 shows the thus obtained relative sample-length changes $\frac{\Delta L_i}{L_{i,0}} = \frac{L_i(T) - L_i(300 K)}{L_{i,0}(300 K)}$ and uniaxial thermal-expansion coefficients $\alpha_i = \frac{1}{L_i} \frac{dL_i}{dT}$, where the index $i$ stands for the direction. The $\frac{\Delta L_i}{L_{i,0}}$ data are in good agreement with previous x-ray studies\cite{18} and show clear evidence for a second-order tetragonal-to-orthorhombic phase transition at $T_s = 87$ K. We note that the $c$-axis anomaly at $T_s$ is unusually small when compared to underdoped Ba(Fe,Co)$_2$As$_2$ (Co-Ba122)\cite{13} or BaFe$_2$(As,P)$_2$(P-Ba122)\cite{14}. The very small anomaly in the volume average of the thermal expansion indicates that $T_s$ does not couple strongly to hydrostatic pressure.
K/GPa, $\frac{dT}{dp_c} = 3.1(1.1)$ K/GPa and $\frac{dT}{dp_a} = 0(0.5)$ K/GPa. The hydrostatic pressure derivative of $T_c$ is simply given by the sum of the uniaxial components $\frac{dT}{dp_c} = \frac{dT}{dp_a} + \frac{dT}{dp_b}$, $T$ (10°K) and is in good agreement with the initial slope of direct measurements, which yield $\frac{dT}{dp_c} = 6 -7$ K GPa$^{-1}$ [19] [20]. It is clear from our results that the comparatively large $\frac{dT}{dp_c}$ in FeSe arises not from particularly large uniaxial components but from lack of their cancellation. The in-plane derivatives are comparable in size to slightly overdoped Co-Ba122 [11, 12]. However, in Co-Ba122, in-plane and c-axis pressure derivatives have opposite signs and largely cancel in the hydrostatic average (with the negative $p_c$ derivative slightly prevailing) [11, 13]. While the uniaxial Grüneisen parameter is five times less sensitive to changes of the in-plane distance alone appears to be the tuning parameter of FeSe. The structural tuning parameter of the uniaxial strain derivatives of the in-plane distance alone appears to be the tuning parameter of its relation to uniaxial pressure effects, this dependence would have to be established.

FIG. 3. (color online) (a) Orthorhombic order parameter $\delta = (a-b)/2a_0$ of FeSe (orange line), undoped Ba122 (dashed black line) and underdoped Co-Ba122 (black line) computed from thermal-expansion measurements. (b) and (c) show $\delta(T)$ of FeSe and Co-Ba122, respectively, below 20 K on a magnified scale. Note that the scale in (b) is ten times smaller than in (c). (d) $\alpha_{a,c}/T$ of FeSe (red and purple lines) and $\alpha_{c}/T$ of underdoped P-Ba122 (dark green line). For clarity, data below $T_c$ are shown in a lighter color. The arrow points at the crossing of the normal-state in-plane thermal-expansion coefficients of FeSe. (e) FeSe a axis 20% P-Ba122 a axis

The maximum of $\delta(T)$ is caused by the sign change of both $\alpha_a(T)$ and $\alpha_b(T)$ at $\sim 12$ K (see inset Fig. 2(c)), which points to an additional low-temperature contribution to the thermal expansion. This contribution, which appears to be diverging down to $T_c$, becomes evident in a plot of $\frac{d\alpha}{dT}$ (Fig. 3(d)). For a Fermi-liquid, one expects a constant $\frac{d\alpha}{dT}$ term at low temperatures, which is directly related to the uniaxial pressure derivative of the Sommerfeld coefficient, as seen for P-Ba122 with 20% P-content [14] (Fig. 3(d)). The non-Fermi-liquid character of the thermal-expansion of FeSe becomes apparent in this comparison. A new energy scale with a negative (positive) contribution to $\frac{d\alpha}{dT}$ ($\frac{dT}{d\alpha}$) emerges below $\sim 30$ K and causes these coefficients to diverge. Note that neither the Knight-shift, nor specific heat have previously shown indications of non-Fermi-liquid behavior [5, 19].

However, thermal-expansion is expected to be an especially sensitive probe for locating such non-Fermi-liquid...
behavior [24] and enhanced low-temperature spin fluctuations have revealed that FeSe is on the brink of a magnetic phase transition near $T = 0$ [5]. Our observation of non-Fermi-liquid behavior is probably related to this quantum critical point and the new energy scale may be linked to the low-temperature spin fluctuations. It is then, however, curious that these fluctuations cause a reduction of the orthorhombic order parameter of FeSe. In the 122-pnictides, in contrast, the onset of magnetism enhances $\delta(T)$ [24], suggesting that the relation between magnetism and orthorhombicity may be different in FeSe.

The very small $ab$-plane anisotropy of $\Delta\alpha_{\parallel}$ of FeSe at $T_c$ implies that $\delta(T)$ has no more than a tiny anomaly at $T_c$, as can indeed be seen in Fig. 3(b). Only a small kink in the temperature derivative $\frac{d\delta}{dT}$ (Fig. 3(d)) is observed, which is such that $\delta$ will have a tendency to be somewhat larger in the superconducting state than in the normal state. In particular, there is no indication of competition between orthorhombicity and superconductivity in FeSe. Such a competitive coupling was clearly observed in underdoped Co-Ba122 (see Fig. 3(c) and Ref. 27) and other doped Ba122-compounds [27] and results in a reduction of $\delta$ below $T_c$, or equivalently in a positive anomaly in $\frac{d\delta}{dT}$ (see Fig. 3(f)). This coupling was proposed to arise, ultimately, from the competition between magnetism and superconductivity [28]. In this scenario, magnetic spin fluctuations, which give rise to “nematic” order that, in turn, induces an orthorhombic distortion via magnetoelastic coupling, are weakened by the onset of superconductivity. It is an important question which part of this scenario is not valid for FeSe. Our results suggest that either superconductivity does not interact strongly with spin fluctuations or that the structural transition has a non-magnetic origin.

In conclusion, high-resolution thermal-expansion measurements of vapor-grown $\beta$-FeSe have revealed a number of unusual properties, which suggest that FeSe is not a typical iron-based superconductor. The structural tuning parameter of FeSe is the in-plane area, compared to the $c/a$ ratio in 122-systems, which explains why $T_c$ couples so strongly to hydrostatic pressure. In underdoped 122 pnictides, magnetism and orthorhombicity are cooperative and compete with superconductivity. In FeSe, on the other hand, $T_c$ and magnetism both increase under hydrostatic pressure, suggesting that they act cooperatively. Further, superconductivity does not compete with orthorhombicity, which raises the question of the origin of the orthorhombic phase transition. Also, we show that a new energy scale, presumably associated with spin fluctuations, emerges at low temperature and slightly reduces the orthorhombic distortion below 12 K. Further studies on the nature of these different phases, which exhibit such an unusual interplay, will be of great interest.

We wish to thank J. Schmalian and R. M. Fernandes for discussions. This work was supported by the DFG under the priority program SPP1458.

[17] Following conventions, we call the shorter orthorhombic $ab$-plane axis $a$, opposed to the prevailing custom in 122-pnictides.
\textsuperscript{22} \( c_{13} \) agrees within 8\% with the experimental low-temperature value of 42.7 GPa\textsuperscript{28} reported from a measurement on thin films. Using the calculated \( c_{ij} \) values, the linear compressibilities \( K_a = \frac{1}{2} \frac{\partial \sigma}{\partial \varepsilon} = K_b = 4.8 \times 10^{-3} \text{ GPa}^{-1} \) and \( K_c = 17.1 \times 10^{-3} \text{ GPa}^{-1} \) are obtained, which are also in relatively good agreement with the experiment (\( K_a = 6.3 \times 10^{-3} \text{ GPa}^{-1} \), \( K_b = 6.9 \times 10^{-3} \text{ GPa}^{-1} \) and \( K_c = 17.6 \times 10^{-3} \text{ GPa}^{-1} \)). Additionally, the elastic properties show relatively little \( ab \)-plane anisotropy.
